Toxicology and Clinical Manifestation of Arsenicosis: An Evaluation

Mohammad A Hye

Professor, Department of Dermatology, Jalalabad Ragib-Rabeya Medical College, Ragib-Rabeya Medical College Road, Patantula, Sylhet-3100, Bangladesh

Abstract
Arsenicosis is an adverse health condition due to prolonged ingestion of arsenic contaminated water. It is most prevalent in Bangladesh. More than 67 million people in Bangladesh are exposed to 0.05 mg/liter or above of arsenic in their drinking water and it is now considered a biggest crisis in health and social sector in the modern world. Arsenicosis affects almost all the vital systems of the body. Skin involvement is the earliest and commonest feature. Major dermatological manifestations are melanosis, keratosis, and skin malignancies. Diagnosis is usually done by history, clinical feature and laboratory analysis.

In this article, the author describes the extent of arsenicosis in Bangladesh and emphasizes dermatological manifestations of the disease.

Keywords: Arsenicosis, Arsenic Contamination, Melanosis, Keratosis, Bangladesh.

Introduction
Arsenicosis is a multisystem disorder due to prolonged exposure of arsenic mainly by drinking water. Chronic toxicity due to ingestion of arsenic contaminated ground water has become a major health problem in Bangladesh. It is now identified in many countries. It is showed that arsenicosis can affect any country irrespective of geographical or economical situation.

The symptoms and signs caused by long-term elevated exposure to arsenic differ between individuals, population groups and geographical areas. There are no internationally recognized criteria for the diagnosis and management of arsenicosis [1]. The purpose of this paper is to review toxicology of this disorder and its related dermatological features in context to Bangladesh.

Toxicology
Arsenic is a natural component of the Earth’s crust. It is found everywhere including atmosphere, soil, rock, water, organism, plant etc. Natural concentrations of arsenic in rock are 1.5-2.0 mg, in contaminated soil up to 500mg/kg and in natural water is 0.1-0.4microgram/L. Arsenic is also emitted into the atmosphere by high-temperature processes such as coal-fired power generation plants, burning vegetation and volcanic action.

Arsenic can combine with both metals and non-metal to form mainly following 2 types of compounds:

1. Inorganic Arsenic, Trivalent, e.g. arsenates, Pentavalent, e.g. arsenates
2. Organic Arsenic, Mono- methyl arsonic acid (MMA), Di-methyl arsanic acid (DMA) etc.

The organic forms are comparatively non-toxic and mostly present in sea foods. Inorganic forms are toxic to human health and present in almost everywhere including air, water, soil and food [2].

After ingestion, arsenic is absorbed from the gastrointestinal tract; following absorption, arsenic undergoes metabolism through repeated reduction and oxidative methylation. It is widely accepted that methylated metabolites of inorganic arsenic are less reactive and less genotoxic; metabolism is regarded as a bio-inactivation mechanism.

Following metabolism, arsenic is rapidly cleared from blood, and only 0.1% of the arsenic remains in the plasma 24 hours after dosing. Urine is the most common route of elimination. As much as 45% to 75% of the dose is excreted in the urine within a few days to a week [3,4]. The trivalent state of arsenic, As 3+, is widely distributed by virtue of its binding with sulfhydryl groups in keratin filament and has a tendency to accumulate in the skin, hair, nails, and mucosae of the oral cavity, esophagus, stomach, and the small intestine [5]. On the other hand, arsenate (As 5+) is the predominant form deposited in the skeleton because of its ability to replaces phosphate in the apatite.
crystal in bones; as a result of this it is retained there for a longer time [5]. Within 30 hours of ingestion, arsenic deposits in the hair. Daily consumption of water with greater than 50 micrograms per liter of arsenics, usually lead to health problems. Some people may be affected by lower levels of arsenic than others. Young children, the elderly, people with long-term illnesses, and unborn babies are at greatest risk of being affected [6].

If the exposure is of a large concentration then the progression of the arsenic poisoning event would lead to seizures, electrolyte disturbances and systemic shock and even death. Trivalent arsenic is believed to be a carcinogen that induces chromosomal abnormalities. However, the exact molecular mechanism of arsenic induced carcinogenesis is less understood [7].

It has been shown to induce sister chromatid exchanges, chromosomal aberrations, and also DNA-protein cross links in lymphocytes and in fibroblasts to explain this genotoxicity, several mechanisms have been put forward, one of which emphasizes the role of reactive oxygen species in inducing the chromatid exchange [8,9]. The other theory highlights the role of arsenic in impairing the DNA repair process. DNA excision repair of thymine dimer in human fibroblast is inhibited by inorganic arsenic As \(^{3+}\) is found to inhibit DNA ligase and tubulin polymerization [10-12]. It has also been shown that arsenic alters the activity of tumor suppressor gene p53 by DNA methylation [13].

**Historical background**

Arsenic is known to human since 400-500 B.C. for its therapeutic use in Greece and Rome. Hippocrates recommended as for treatment of skin ulcer & boil. In Indian sub-continent during the period of Buddha, it had been used for the treatment of many diseases. Alchemiste Geber-discovered arsenic oxide in 9th century. The poison was transformed into a medicine in the 1700s, when Thomas Fowler developed a solution of arsenic trioxide in potassium bicarbonate (1%w/v) for the treatment of asthma, chorea, eczema, pemphigus, and psoriasis [14]. It was also used empirically for the treatment of a variety of diseases, including leprosy, syphilis, and yaws [15].

In 1822 as was identified as possible carcinogen. Interestingly enough, the dilemma of its effects and side effects is still going on; in spite of health crisis due to arsenic poisoning, in many countries, arsenic trioxide (trisenox) has been used in the treatment of patients with acute promyelocytic leukemia in modern time and has even obtained the FDA approval in September 2000 for use in the condition [14,16].

It is colorless, odourless, and tasteless and these characteristic contributed much to use it as a poison of choice. Arsenic poisoning, accidental or deliberate has been implicated in the illness or death of a number of people throughout the history. Recent forensic evidence uncovered the evidences of arsenic poisoning as a cause of death of following prominent people: Francesco I de Medici, Grand duke of Tuscany (1541-1587), Eric VII of Sweden(1533-1577), George III of Great Britain (1738-1820), Theodor Ursinus (1749-1800), Napoleon Bonaparte (1769-1821) [17].

**Arsenicosis case definition**

WHO working group defined Arsenicosis as “a chronic condition arising from prolonged ingestion of arsenic above safe dose for at least six months, usually manifested by characteristic skin lesions of melanosis and or keratosis with or without involvement of internal organs” [18].

The WHO Guideline value for arsenic in drinking water is set at 10 ppb. This is the drinking water standard adopted in many industrialized countries. However many developing countries have kept the limit at 50 ppb for practical reasons [1].

**Arsenicosis in bangladesh**

“Bangladesh is in the midst of a mass poisoning in history, dangerous level of arsenic have been found in the ground water, entering millions of people sip by sip as they drink from over 4 million tube wells.”

Prior to the 1970s, Bangladesh had one of the highest infant mortality rates due to ineffective water purification sewage system. Millions of wells were constructed then to provide drinking water. In result, infant mortality and diarrheal diseases were reduced by 50%. But among 8.4 million wells, approximately 1 in 4 of these wells is now contaminated with arsenic. So far ground water contamination by arsenic is detected in 62 districts out of 64 and about 38200 arsenicosis patients were identified across the country [19].

Arsenicosis was first reported in Chapai Nawabgonj district in year 1993. Now, it is estimated that between 35 to 77 million Bangladeshi or 28 to 62% of the total population of 125 million are now at risk of chronic arsenic poisoning [19]. It is described in world media as the largest known mass poisoning in history [20].

**Global scenario of arsenic contamination**

Arsenic contamination of groundwater is widespread and there are a number of regions where arsenic contamination of drinking-water is significant. It is now recognized that at least 140 million people in 50 countries have been drinking water containing arsenic at levels above the WHO provisional guideline value of 10 µg/L [21].

In 1917, chronic arsenicism (Arsenicosis) through ground water was first identified in Cordoba of Argentina (Bell Ville Disease). High concentrations of arsenic in drinking-water are found in various parts of the world including Argentina, Bangladesh, Chile, China, Hungary, India (West Bengal), Mexico, Nepal, Pakistan, Thailand, USA, and Viet Nam. It may be mentioned that in USA, and many other countries safe level of arsenic is below 0.01mg/l [22].

**Skin manifestations**

Arsenicosis can cause a numbers of adverse condition in health, including dermal lesions, peripheral neuropathy, skin cancer, bladder and lung cancers and peripheral vascular disease [23-28]. Increased risks of above mentioned skin disorder have been reported to be associated with ingestion of drinking-water at concentrations ≤50 µg arsenic/litre [7].

Usually dermatological manifestations start to appear after minimum exposure periods of approximately 5 years. It may be 80% of them with urinary excretion of arsenic value between 1-3 mg/l [29]. In one large-scale study, 3695 (20.6%) of 18,000 persons in Bangladesh and 8500 (9.8%) of 86,000 persons in West Bengal living in arsenic-affected districts were found to show dermatological features of arsenicosis [29]. Pigmentary changes (melanosis) and hyperkeratosis are the predominant cutaneous effects; though at times, Bowen’s disease or skin cancers may arise too.
Epidemiological studies in different regions of the world have consistently demonstrated a strong association between long-term inorganic arsenic ingestion and skin lesions, typically in the form of hyperkeratosis, hyperpigmentation or hypopigmentation. Observations of skin lesions following low chronic exposure have suggested that these characteristic dermal changes are sensitive indications of the toxic effects of inorganic arsenic [30].

These effects have been demonstrated in many studies using different study designs. Exposure–response relationships and high risks have been observed for each of these end-points. The effects have been most thoroughly studied in Taiwan [31]. In this large study, a population of 40,421 was divided into three groups based on the arsenic content of their well water (high, >0.60 mg/l; medium, 0.30–0.59 mg/l; and low, <0.29 mg/l) (Tseng, 1977) [31]. There was a clear dose–response relationship between exposure to arsenic and the frequency of dermal lesions, “black foot disease” (a peripheral vascular disorder and pigmentation) and skin cancer. However, in this study, there were several methodological weaknesses which complicate the interpretation of the results. In addition, the possibility of other causes of black foot disease were not considered [32].

There are also considerable evidences from other studies in different countries. A similar exposure–response pattern was observed in a study in Bangladesh, where prevalence of keratosis was used as a surrogate for arsenic exposure [33,34].

Dermatological lesions are classified or described different ways in different studies. GuhaMazumdar et al described skin lesions of arsenic in following way [35]:

<table>
<thead>
<tr>
<th>Grade-I Mild</th>
<th>Grade-II Moderate</th>
<th>Grade-III Severe</th>
</tr>
</thead>
<tbody>
<tr>
<td>a. Diffuse melanosis.</td>
<td>a. Define definite spotty pigmentation/depigmentation on the trunk and limbs, bilaterally distributed.</td>
<td>a. Define definite spotty pigmentation/depigmentation as above with few blotchy pigmented/igmented macular patches over trunks or limbs</td>
</tr>
<tr>
<td>b. Suspicious spotty depigmentation/depigmentation over trunk/limbs</td>
<td>b. Severe diffuse thickening (with/without wart like nodules of the palms and soles).</td>
<td>b. Pigmentation involving the undersurface of tongue and/or buccal mucosa.</td>
</tr>
<tr>
<td>c. Mild diffuse thickening of soles and palms.</td>
<td></td>
<td>c. Larger nodules over thickened palms and soles. Diffuse verrucous lesions of the soles with cracks and fissures and keratotic horns over palms/soles.</td>
</tr>
</tbody>
</table>

Dermatological lesions are classified or described different ways in different studies.

Followings are the Major Dermatological Manifestations

**Melanosis:** The earliest and the commonest cutaneous sign is melanosis [36,37]. In a study, conducted in the arsenic-prevalent area of Bangladesh, 100% of the patients of arsenocolsis showed pigmentary changes [37]. Prolonged ingestion of arsenic results in pigmentation, most intense on the trunk, which can be diffused; or localized, particularly affecting skin folds [7,38,39]. Fine freckles of spotted pigmented changes are also seen, known as ‘rain-drop pigmentation’ [Fig.2] Sometimes macular areas of depigmentation may appear on normal skin or hyperpigmented background producing the distinctive appearance of ‘leucomelanosis’ [Fig.3] [7,38,39].

Figure 1: Melanosis

**Rain drop pigmentation**

Figure 2: Rain drop pigmentation
Figure 3: Leukomelanosis

Blotchy pigmentation may also involve mucous membranes such as the undersurface of the tongue or buccal mucosa [7,38,39].

**Keratosis:** Arsenical hyperkeratosis appears predominantly on the palms and soles, and it has been found that keratosis on the soles is the most sensitive marker for the detection of arsenicosis at an early stage [40]. Keratoses are graded as mild, [Fig.4] moderate, or severe depending on the extent and severity [7].

**Figure 4: Mild Keratosis**

In the mild variety of keratosis, the involved skin has an hardened texture with papules less than 2 mm in size [Fig.4] that can be best felt by palpation. In the moderate variety, the lesions usually advance to form raised, punctate, keratosis, 2-5 mm in [Fig.5] When the keratosis becomes severe, it may form keratotic elevations more than 5 mm in size and sometimes become confluent and diffuse [Fig6] and sometimes result in cracks and fissures too [36,41]. [Fig.7]

**Figure 5: Moderate Keratosis**

**Figure 6: severe Keratosis**

Though palms and soles are primarily affected by hyperkeratosis, dorsa of the extremities and trunk may also be affected by it. It is interesting that palmar keratosis usually appear earlier than arsenic-related cancers of bladder and lung; thus it can act as an early marker of carcinogenicity [42].

**Skin Cancers:** Usually three types of skin cancers are observed: Bowen’s disease; basal cell carcinoma and squamous cell carcinoma. In Japan, a study showed that Bowen’s disease develop after 10 years, invasive squamous cell carcinoma develop after 20 years and internal malignancy particularly pulmonary malignancy develop after 30 years of arsenic exposure [43].

It has been suggested that human papilloma virus (HPV) infection could constitute an additional risk factor for the development of non-melanoma skin cancer in humans chronically exposed to as [44]. There are also published reports of Merkel cell carcinoma, sometimes arising in association with Bowen’s disease in patients with arsenicosis [45-47]. There is also a study which has demonstrated an increased risk of melanoma in persons with elevated toenail arsenic concentrations, raising the issue relating to the role of arsenic in the development of melanoma [48]. Skin cancer in arsenicism can arise in the hyperkeratotic areas, [Fig.8] as well as appear on non-keratotic areas of the trunk, extremities, [Fig-9] or head [49,50].

**Figure 7: severe Keratosis with crack and fissure**

**Figure 8: Squamous cell carcinoma**
Skin is thought to be perhaps the most sensitive site for arsenic-induced malignancies [51]. The lesions are frequently multiple and involve covered areas of the body; unlike non-arsenical skin cancer, which usually presents as a single lesion and which occurs frequently on the exposed parts of the body [31,52].

**Histopathological feature**

There is a paucity of reports regarding the types and patterns of histopathological changes in skin lesions of chronic arsenicosis. A study from Bangladesh documented that hyperkeratosis, parakeratosis, acanthosis, papillomatosis, hypergranulosis, and dysplastic changes to be the most important and constant findings [53]. However, basal pigmentation and dermal changes were found to be inconsistent features.

In another study, hyperkeratotic lesions of 70 patients with arsenicosis were compared with 20 controls [54]. Significant findings included hyperkeratosis (100%), parakeratosis (97%), acanthosis (95.7%), and papillomatosis (74%). The results were found to be significantly more (P < 0.001) in the patients than in controls. Basal cell pigmentation was found in 42.8% (P > 0.05) and dysplasia and malignant changes in 7% (P > 0.1). There is no study about the histopathology of arsenic-related pigmented lesions.

A study on the neoplastic manifestations of arsenicosis revealed pre-cancerous skin lesions in 6.6% and cancerous lesions in 0.8% of the patients [55].

**Conclusion**

Arsenicosis is a health crisis for millions of people of Bangladesh and part of India. The extent and magnitude of the problem is really high. The risks of this disease not only confined in this region but many others countries may experience the same in future.

Current knowledge and technology are not good enough to address the burning problem of arsenicosis. Clinicians, scientists and health personnel, irrespective of any country, region or nationality, should be more oriented and co-ordinated in the fight against the curse of arsenicosis.
